Abstract. Algebraic attacks on stream ciphers [9] recover the key by solving an overdefined system of multivariate equations. Such attacks can break several interesting cases of LFSR-based stream ciphers, when the output is obtained by a Boolean function, see [9–11]. Recently this approach has been successfully extended also to combiners with memory, provided the number of memory bits is small, see [1, 11, 2]. In [2] it is shown that, for ciphers built with LFSRs and an arbitrary combiner using a subset of k LFSR state bits, and with l state/memory bits, a polynomial attack always do exist when k and l are fixed. Yet this attack becomes very quickly impractical: already when k and l exceed about 4. In this paper we give a much simpler proof of this result from [2], and prove a more general theorem. We show that much better algebraic attacks exist for ciphers that (in order to be fast) output several bits at a time.

In practice our result substantially reduces the complexity of the best attack known on three well known constructions of stream ciphers when the number of outputs is increased. We present attacks on modified versions of Snow, E0 and LILI-128 that are apparently the fastest known.

Key Words: LFSR-based stream ciphers, algebraic attacks on stream ciphers, pseudo-random generators, multivariate equations, overdefined problems, linearization, XL algorithm, nonlinear filtering, Boolean functions, combiners with memory, LILI-128, Snow, Nessie, E0, Bluetooth.

1 Introduction

In this paper we study LFSR-based stream ciphers. In such ciphers there is a state updated by an iterated linear function, and a stateful or stateless nonlinear combiner that produces the output, given the state of the first (linear) part. In particular, we are interested in the case when the combiner has several outputs, which seems to be a good idea in order to obtain ciphers that will be fast in practice.

For stateless combiners - using a Boolean function, the general attacks that are known are mainly the correlation attacks, see for example [21, 16, 7]. In order to resist such attacks, many authors focused on proposing Boolean functions that will have no good linear approximation and that will be correlation immune with regard to a subset of several input bits, see for example [7]. Unfortunately there is a tradeoff between these two properties. One of the proposed remedies is to use a stateful combiner. This idea is used in the Bluetooth wireless protocol cipher E0 [4]. Yet the simplicity of E0 did not prevent the existence of advanced correlation attacks [18] and other attacks [2, 1, 11].

Recently the scope of application of the correlation attacks have been extended to consider higher degree correlation attacks with respect to non-linear low degree multivariate functions, or in other words, allowing to exploit low degree approximations [9]. The paper [9], proposes an algebraic approach to the cryptanalysis of stream ciphers. It will reduce the problem of key recovery, to solving an overdefined system of algebraic equations. Following [9] and [10], all LFSR-based stream ciphers are (potentially) vulnerable to algebraic attacks. The argument says that, if by some method, we are able to deduce from the output bit(s), only one multivariate equation of low degree in the state bits, then the same can (probably) be done for many other states. Each equation remains also linear with respect to any other state, and given many keystream bits, we inevitably obtain a very overdefined system of equations (i.e. many equations). Then we may apply the XL algorithm from Eurocrypt 2000 [27], adapted for this purpose in [9], or the simple linearization as in [10], to efficiently solve the system.

In the paper [10], the scope of algebraic attacks is substantially extended, by showing new non-trivial methods to obtain low degree equations, that are not low degree approximations. This gives attacks that are not correlation attacks anymore, and are purely algebraic attacks on stream ciphers. The method to reduce the degree of the equations, is analogous to the method proposed by Courtois and Pieprzyk to attack some block ciphers [13], and the basic idea goes back to [12] and [25]. Instead of considering outputs as functions of inputs, one should rather study multivariate relations between the input and output bits. They turn out to have a substantially lower degree.

In most cases, due to the recursive structure of the cipher, finding just one such relation will give a polynomial attack. Surprisingly, this "multivariate relation" approach from [10] may be applied also to combiners with memory, in particular when the number of possible states is small. This can be seen as continuation of previous results by Meier and Staffelbach on correlation attacks on combiners with one memory bit [22], extended to several memory bits by Golic in [17]. For algebraic attacks, the possibility of eliminating memory bits has been first suggested by Courtois [10], but the heuristics only says that such attacks may exist, and exhibits also a counter-example for which the current method will fail to find a useful multivariate relation that would lead to an attack (cf. Section 7 of [10]). Yet, considering relations that imply potentially many output bits, seems very promising, except that finding useful relations becomes a hard problem (how to know which outputs will be used in the relation?). The first attack of this type for a realistic stream cipher E0, has been found by careful elimination by hand, done by Armknecht [1]. A substantial speed-up for this attack is described by Courtois in [11].

Even more surprisingly, Krause and Armknecht have recently proven a Theorem, to the effect that for **any** combiner with k inputs and l bits of memory, an algebraic attack of this type will always exist [2]. More precisely, they show that required multivariate relations do always exist with degree at most $\lceil k(l+1)/2 \rceil$. This generalises an earlier theorem due to Courtois and Meier, giving degree $\lceil k/2 \rceil$ for $l = 0$, published in [10].

This result means that starting from about $l = 4$ memory bits, algebraic attacks will quickly become impractical. In this paper we will give a new, much simpler proof of this theorem. We will also prove a more general theorem, for combiners with several outputs, that allows to substantially lower the degree of resulting relations, which can dramatically decrease the complexity of attacking certain stream ciphers. Our theorem will also give new and valuable results for combiners without memory (i.e. using just Boolean functions).

2 Notation

We consider a stream cipher in which there is a state with a linear feedback function (for example composed of one or several LFSRs). Let $k = (k_0, \dots, k_{n-1})$ be an n -bit secret key. Let $s = k$ be the initial state of the linear part of the cipher. At each clock, the state is computed as $s \leftarrow L(s)$ with L being some multivariate linear transformation, for example corresponding to the connection polynomial of an LFSR, or a combination of several parallel LFSRs. We assume that L is public.

We assume that k out of n bits are used in the next stage of the cipher that is called the combiner. We call these bits the $x_0^{(t)}, \dots, x_{k-1}^{(t)}$ which are a fixed subset of the $s_0^{(t)}, \dots, s_{n-1}^{(t)}$.

The combiner has l bits of internal state (for stateless combiners $l = 0$) that are denoted by $a_0^{(t)}, \dots, a_{l-1}^{(t)}$. The initial state can be anything (it is unknown).

We also assume that the combiner has m bits of output (usually $m = 1$). We denote these outputs by $y_0^{(t)}, \dots, y_{m-1}^{(t)}$.

In the general case, the combiner is a pair of functions $F = (F_1, F_2) : GF(2)^{k+l} \rightarrow GF(2)^{m+l}$, that given the current state and the input, computes the next state and the output:

$$F : \begin{cases} (y_0^{(t+1)}, \dots, y_{m-1}^{(t+1)}) = F_1(x_0^{(t)}, \dots, x_{k-1}^{(t)}, a_0^{(t)}, \dots, a_{l-1}^{(t)}) \\ (a_0^{(t+1)}, \dots, a_{l-1}^{(t+1)}) = F_2(x_0^{(t)}, \dots, x_{k-1}^{(t)}, a_0^{(t)}, \dots, a_{l-1}^{(t)}) \end{cases}$$

3 Algebraic Attacks on Stream Ciphers

We recall that the linear part of our cipher (a combination of one or several binary LFSRs) is composed of n bits s_0, \dots, s_{n-1} . At the beginning $s = k$ (the initial state) and at each clock of the cipher, it is updated as $s \leftarrow L(s)$, with L being some known multivariate linear transformation. The general algebraic attack on such stream ciphers, following closely [10] or [11], works as follows:

- Find (by some method that is very different for each cipher) one (at least, but one is enough) multivariate relation Q of low degree d between the state bits and some M following outputs, for example:

$$Q(s_0, s_1, \dots, s_{n-1}, y^{(0)}, \dots, y^{(M-1)}) = 0$$

- The same equation will apply to all consecutive windows of M states

$$Q([L^t(k)]_0, [L^t(k)]_1, \dots, [L^t(k)]_{n-1}, y^{(t)}, \dots, y^{(t+M-1)}) = 0$$

- The $y^{(t)}, \dots, y^{(t+M-1)}$ are replaced by their values known from the observed output of the cipher.
- Due to the linearity of L , the degree of these equations is still d .
- Given many keystream bits, we inevitably obtain a very overdefined system of equations (i.e. great many multivariate equations of degree d in the k_i).
- Then we may apply the XL algorithm from Eurocrypt 2000 [27], adapted for this purpose in [9].
- If we dispose of a sufficient amount of keystream, (which is frequently not very big, see [10]), the XL algorithm may be replaced by the so called linearization method that is particularly simple. There are about $T \approx \binom{n}{d}$ monomials of degree $\leq d$ in the n variables k_i (assuming $d \leq n/2$). We consider each of these monomials as a new variable V_j . Given about $\binom{n}{d} + M$ keystream bits, and therefore $R = \binom{n}{d}$ equations on successive windows of M bits, we get a system of $R \geq T$ linear equations with $T = \binom{n}{d}$ variables V_i that can be easily solved by Gaussian elimination on a linear system of size T .
- In theory, the relinearization step takes time T^ω with $\omega \leq 2.376$ [8]. However the fastest practical algorithm we are aware of, is Strassen's algorithm [29] that requires about $7 \cdot T^{\log_2 7}$ operations. Since our basic operations are over $GF(2)$, we expect that a careful bitslice implementation of this algorithm on a modern CPU can handle 64 such operations in one single CPU clock. To summarize, in this paper we assume that the Gaussian reduction takes $7 \cdot T^{\log_2 7} / 64$ CPU clocks.

4 The Proof Method

Our general Theorem 5.1, given later, considers arbitrary combiners with k input bits, l memory bits, and m output bits and shows the existence of equations of some degree that lead to an algebraic attack. It generalises the main result of [2] for arbitrary combiners with one output, i.e. with $m = 1$, which in turn generalises a result obtained in [10] for memoryless combiners with single output, i.e. for $m = 1$ and $l = 0$. Our proof technique is very different than in [2] and is very similar to one used in [10].

In this section, in order to illustrate the simplicity of our proof technique, we will first prove the following theorem for combiners with $m = 1$ and $l = 1$, that is in fact a special case of both our general Theorem 5.1 given later, and of the main theorem of [2].

Theorem 4.1 (Special Case of Krause-Armknecht Theorem).

Let F be an arbitrary fixed circuit/component with k binary inputs x_i , one bit of memory a , and one output y . In other words, the output and the next state of the memory bit

a , depend in an arbitrary way (but deterministically) on the k inputs and the previous memory bit.

Then, given $M = 2$ consecutive states $(t, t + 1)$, there is a multivariate equation R of degree k in the $x_j^{(i)}$, that relates only the input and the output bits, **without** any of the state/memory bits $a^{(t)}, a^{(t+1)}$, as follows:

$$R\left(x_0^{(t)}, \dots, x_{k-1}^{(t)}; x_0^{(t+1)}, \dots, x_{k-1}^{(t+1)}; y^{(t)}, y^{(t+1)}\right) = 0.$$

Remark: In this and later theorems, we will only limit the degree of the equations in the $x_j^{(i)}$. The degree in the $y_j^{(i)}$ is not important, as in an attack these values will be fixed.

Proof: We consider $2k$ variables as follows: $x_0^{(t)}, \dots, x_{k-1}^{(t)}, x_0^{(t+1)}, \dots, x_{k-1}^{(t+1)}$. We know that the following two memory bits $a^{(t)}$ and $a^{(t+1)}$ and the two outputs $y^{(t)}, y^{(t+1)}$, do depend only on these $2k$ variables, plus additionally on the bit $a^{(t-1)}$ present in memory at the beginning. Thus, the four values $a^{(t)}, a^{(t+1)}, y^{(t)}$ and $y^{(t+1)}$, do depend deterministically only on the $2k + 1$ variables $x_0^{(t)}, \dots, x_{k-1}^{(t+1)}$ and $a^{(t-1)}$. This is summarised on the following picture:

Fig. 1. Two successive applications of a combiner with k inputs, 1 output and 1 memory bit

We define the following set of monomials A : we consider all the monomials of degree up to k in the following $2k$ variables: the $x_i^{(t)}$ together with the $x_j^{(t+1)}$. The size of A is exactly $\sum_{i=0}^k \binom{2k}{i} = 2^{2k-1} + \frac{1}{2} \binom{2k}{k}$, which is strictly greater than 2^{2k-1} .

Now we will create the following matrix:

- Lines are all the possibilities for $x_0^{(t)}, \dots, x_{k-1}^{(t)}, x_0^{(t+1)}, \dots, x_{k-1}^{(t+1)}$ and for the memory bit $a^{(t-1)}$. There are 2^{2k+1} lines.
- The columns are all products of monomials of A , multiplied by any out of the 4 possible monomials in the two variables $y^{(t)}, y^{(t+1)}$. There are $4 \cdot |A| = 2^{2k+1} + 2 \binom{2k}{k} > 2^{2k+1}$ columns.
- Each entry in the matrix is the value $\in \{0, 1\}$ of the column monomial in the case corresponding to the current line.

The number of columns is strictly greater than the number of lines. Therefore one column must be a linear combination of other columns. Since columns are products of monomials,

and all the cases are treated, this gives a multivariate equation, true with probability 1, for all possible entries and whatever is the initial value of $a^{(t-1)}$. By construction, it does not involve memory bits $a^{(i)}$. This ends the proof of Theorem 4.1. \square

Remark 1: It can be seen that there are at least $2^{\binom{2k}{k}} - 1$ such equations, which could greatly reduce the keystream requirements of some attacks. For simplicity we do not exploit this in the present paper.

Remark 2: In Appendix A, we give another proof of this Theorem, in which the result will be a bit stronger: in the above theorem, there are arbitrary products of degree k of the $x_i^{(t)}$ and the $x_j^{(t+1)}$, that are multiplied by one of the 4 possible monomials $1, y^{(t)}, y^{(t+1)}, y^{(t)}y^{(t+1)}$. Surprisingly, it is sufficient to consider products that do not mix the input/output variables for the first step t , with any of the variables for the second step $t + 1$. This results in much less monomials being present.

The two remarks above show that there is still room for improvement in general algebraic attacks on stream ciphers.

5 New General Result on Combiners with Memory

We use the same method to prove our main result generalising the main theorem of [2].

Theorem 5.1 (Our Key Theorem).

Let F be an arbitrary fixed circuit/component with k binary inputs x_i , l bits of memory a_i , and m outputs y_i . Let d and M be two integers such that:

$$2^{Mm} \cdot \sum_{i=0}^d \binom{Mk}{i} > 2^{Mk+l} \quad (\mathbf{K})$$

Then, considering M consecutive steps/states $(t, \dots, t + M - 1)$, there is a multivariate equation (and relation) R of degree d in the $x_j^{(i)}$, relating ¹ the input and the output bits for these states

$$R \left(x_0^{(t)}, \dots, x_{k-1}^{(t)}, \dots, x_0^{(t+M-1)}, \dots, x_{k-1}^{(t+M-1)}; \right. \\ \left. y_0^{(t)}, \dots, y_{m-1}^{(t)}, \dots, y_0^{(t+M-1)}, \dots, y_{m-1}^{(t+M-1)} \right) = 0.$$

Proof: Our proof is very similar as in the special case above (Theorem 4.1), and also gives a new, much simpler proof of the original (less general) result from [2].

We start with the following:

- We have $M \cdot m$ output bits: $y_0^{(t)}, \dots, y_{m-1}^{(t)}; \dots; y_0^{(t+M-1)}, \dots, y_{m-1}^{(t+M-1)}$
- The total of $M \cdot k$ input bits, $x_0^{(t)}, \dots, x_{k-1}^{(t)}; \dots; x_0^{(t+M-1)}, \dots, x_{k-1}^{(t+M-1)}$.
- We have l initial memory bits, $a_0^{(t-1)}, \dots, a_{l-1}^{(t-1)}$.
- In all we have $l + Mk$ input variables. The memory bits for second and following states, $a_j^{(t+i)}$, $0 < i < M$ do depend only on these $l + Mk$ variables.

¹ Again, **without** any of the state/memory bits $a_j^{(i)}$.

- Thus, for our M consecutive steps/states $t, \dots, t+M-1$, all the outputs $y_j^{(t+i)}$, $i < M$ do depend deterministically only on the $l + Mk$ variables listed above.

This is summarised on the following picture:

Fig. 2. M successive applications of a combiner with k inputs, m outputs and l bits of memory

We define the following set of monomials A : we consider all the monomials of degree up to d in all the Mk variables $x_i^{(t+i)}$. The size of A is exactly $\sum_{i=0}^d \binom{Mk}{i}$. Now we will create the following matrix:

- Lines are all the possibilities for the $l + Mk$ input variables. There are 2^{Mk+l} lines.
- The columns are all products of monomials of A , multiplied by any of possible monomials in the $y_j^{(t+i)}$. There are $2^{Mm} \cdot |A| = 2^{Mm} \cdot \sum_{i=0}^d \binom{Mk}{i}$ columns.
- Each entry in the matrix is the value $\in \{0, 1\}$ of the column monomial in the case corresponding to the current line.

The key argument is the same as before. The number of columns in our matrix should be strictly greater than the number of lines, and the requirement to achieve this, is precisely our previous assumption:

$$2^{Mm} \cdot |A| = 2^{Mm} \cdot \sum_{i=0}^d \binom{Mk}{i} > 2^{Mk+l}$$

Therefore we get at least one non-trivial linear combination of columns (i.e. monomials) that is zero, for all possible entries and all possible initial (memory) states. This multivariate equation is (with the monomials we have chosen) exactly of the form required by our Theorem 5.1, and this ends the proof. \square

6 Theorem 5.1 vs. Algebraic Attacks on Stream Ciphers

Theorem 5.1 and other results of this paper, allow to find equations and execute the algebraic attack described in Section 3. In some cases this Theorem would work even when $d = 0$, when other variables are such that (K) holds, but the equations of degree 0 in the $x_j^{(i)}$ will only contain the $y_j^{(i)}$, and cannot be used to recover the secret key of a cipher (though can probably be exploited to predict the future keystream). For simplicity, in this paper we will always apply Theorem 5.1 for $d \geq 1$.

6.1 The Complexity of the Attacks based on Theorem 5.1

Our algebraic attack on stream ciphers has two main steps:

Step 1. Find the equations by Gaussian reduction on the matrix given in the proof of the Theorem. This step requires about $2^{\omega(Mk+l)}$ computations.

Step 2. From the Step 1. for each keystream bit, we get one equation of degree d in the $x_j^{(i)}$ (with $d \geq 1$). The $x_j^{(i)}$ are known linear combinations of the key bits k_i and these equations are also of degree d in the key bits. When the $x_j^{(i)}$ are replaced by their actual values obtained from the keystream, we get multivariate equations that only contain monomials of degree k in the key bits k_i . Then, given about $T = \binom{n}{d}$ keystream bits, we solve these equations by linearization in about $T^\omega \approx 2^{\omega d \log n}$ computations.

In some cases (when M is small), the complexity of the first step may be negligible compared to the second step (cf. Section 7.5 and examples in Table 2). In some cases the complexity of the first step may always be very large (examples in Table 3). In other cases there will be a tradeoff between the complexity of the two steps, see Section 7.6.

Remark: The complexity of replacing in the equations of Step 1., of the $x_j^{(i)}$ by the relevant linear combinations of the key bits k_i (cf. Section 3) is neglected for simplicity (it can be seen to be smaller than the maximum of complexities given above).

6.2 Important Remark

It is important to understand that, in general, this Theorem 5.1 does not show that the algebraic attack will always work. There are some (very special) cases in which it will not work as well as expected from our Theorem 5.1. We will see this on an example.

Assume that we have a component that has $l = 10$ outputs, and we artificially add 10 more outputs computed as some 10 Boolean functions of the "real" outputs:

$$(y_{10}, \dots, y_{19}) = (F_{10}(y_0, \dots, y_9), \dots, F_{19}(y_0, \dots, y_9)).$$

Now we have (in theory) $l = 20$, and from the formula (K) we see easily that in most cases our Theorem 5.1 will give for $m = 20$ equations of substantially lower degree than for $m = 10$. These equations are real (their existence is proven). Yet these equations will not be useful in an attack. For example there will be equations such as $y_{10} = F_{10}(y_0, \dots, y_9)$, and a great many of derived equations: different linear combinations of these equations multiplied by many different monomials. All these equations are in a sense "artificial" and unfortunately they will all reduce to 0 later in the attack, after when the y_0, \dots, y_{19} are replaced by their values obtained from the output of the cipher.

This example shows that in some very special cases, the algebraic attack will probably not work for the degree given by our Theorem 5.1. Yet, it will probably work perfectly well for the degree corresponding to the "real" value of $l = 10$. It is conjectured that when the output bits are fully independent and not related by some algebraic relation, and if the output takes all the possible 2^m values, the attack should always work, for **every** equation obtained from the above Theorem 5.1. Moreover, in practice, the difference

between the number of lines and the number of columns, in the matrix (the one we generated to prove the theorem) will be big, and there will be not only one but, (for example) thousands of equations obtained. The chances that the attack would not work for all of them, are probably negligible.

7 How to Use Theorem 5.1 - Looking For Optimal Algebraic Attacks

In the previous Section 6 we showed that it is straightforward to use Theorem 5.1 to design an algebraic attack on stream ciphers following Section 3. Another question is to choose parameters in such a way that the complexity of the attack will be optimal. For this we need to study the behaviour of the key inequality (K): $2^{Mm} \cdot \sum_{i=0}^d \binom{Mk}{i} > 2^{Mk+l}$. In order to minimise the complexity of Step 2. of the attack (cf. Section 6.1) we simply need to choose M that gives the smallest possible d . Yet, as we will see later (in particular when $m \geq k$, cf. Section 7.6) things are not always as simple to optimise the Step 1.

7.1 Asymptotic Behaviour of (K) and Theorem 5.1

In order choose (M, d) that satisfy (K): $2^{Mm} \cdot \sum_{i=0}^d \binom{Mk}{i} > 2^{Mk+l}$ we have two cases:

- A. If $m < k$, when $M \rightarrow \infty$ we have no hope to satisfy the key inequality (K). In this case we conjecture that the best attack (and the smallest degree d) will be achieved taking M as small as possible (or close to it). This case is studied in Section 7.5.
- B. If $m \geq k$ then when $M \rightarrow \infty$ we can always satisfy the key inequality (K). In this case we should take M as big as possible, but not too big because the complexity to find the equations required by the attack (Step 1. cf. Section 6.1) could become bigger than the complexity of the attack itself (Step 2.). This case is studied in Section 7.6.

Remark: For the (less general) theorem from [2], there is only the case A., because $m = 1$.

7.2 Necessary Condition for (K) and Theorem 5.1

We want to solve (K) given the values m and l . Since one always has $\sum_{i=0}^d \binom{Mk}{i} \leq 2^{Mk}$, we cannot have $Mm \leq l$, and this gives a **necessary condition** $Mm > l$, hence $Mm \geq l + 1$ which gives

$$M \geq \lceil (l + 1)/m \rceil. \quad (C)$$

7.3 Sufficient Conditions for (K) and Theorem 5.1

Conversely, it is easy to see that, each time $M \geq \lceil (l + 1)/m \rceil$, we have $Mm \geq l + 1$, and the formula (K) will be satisfied for some $d \leq Mk$.

Sufficient Condition 1: For any given values m and l , and for any $M \geq \lceil (l + 1)/m \rceil$, the formula (K) will be satisfied by some d being at most $d \leq Mk$.

When the minimum $M = \lceil (l + 1)/m \rceil$ is chosen, we can use $d = k \cdot \lceil (l + 1)/m \rceil$, but in fact one can do better. A smaller d can be achieved for this same (minimal) M . Indeed, since M is an integer, the minimal value of M does not imply that we need to take a maximal value for d . From (K) we get the following condition:

$$\sum_{i=0}^d \binom{Mk}{i} > 2^{Mk} \cdot 2^{l-m \cdot \lceil (l+1)/m \rceil}$$

It can be seen that $d = \lceil kM/2 \rceil = \lceil k\lceil(l+1)/m\rceil/2 \rceil$ is always sufficient. Indeed we always have

$$\sum_{i=0}^d \binom{Mk}{i} > 2^{Mk}/2.$$

And we also always have

$$\frac{1}{2} \geq 2^{l-m \cdot \lceil(l+1)/m\rceil}.$$

Sufficient Condition 2: From the above, we get immediately the following Theorem:

Theorem 7.4 (Generalised Krause-Armknecht Theorem).

Let F be an arbitrary fixed circuit/component with k binary inputs, l bits of memory, and m outputs. Then, considering $M = \lceil(l+1)/m\rceil$ consecutive steps/states $(t, \dots, t+M-1)$, there is a multivariate relation, involving only the input bits (the $x_j^{(i)}$) and the output bits (the $y_j^{(i)}$) for these states, and with degree $\lceil kM/2 \rceil = \lceil k\lceil(l+1)/m\rceil/2 \rceil$ in the $x_j^{(i)}$.

Remark: If we put $m = 1$ in this Theorem 7.4 (1 output bit), we obtain exactly the main result of [2]. This in turn generalises the theorem given in [10], which is exactly the above result with $m = 1$ and $l = 0$, i.e. the case of Boolean functions that are memoryless combiners with 1 output bit.

7.5 How to Use Theorem 5.1 when $m < k$

All the remarks above are true both for $m < k$ and for $m \geq k$, however we expect that (cf. Section 7.1) choosing the smallest possible M should be optimal (or close to optimal) only when $m < k$.

In some cases, the choice of Theorem 7.4 above: $M = \lceil(l+1)/m\rceil$ and $d = \lceil kM/2 \rceil$ will be optimal for Theorem 5.1. However in most cases, there will be a non-zero difference between $M = \lceil(l+1)/m\rceil = 1$ and $(l+1)/m$ that will imply that $\frac{1}{2} \gg 2^{l-m \cdot \lceil(l+1)/m\rceil}$ in the derivation of Theorem 7.4 above. In such cases, it seems that the best method² is take still $M = \lceil(l+1)/m\rceil$ (or very close to this) and try to the lowest d that satisfies the key requirement of Theorem 5.1 which is $2^{Mm} \sum_{i=0}^d \binom{Mk}{i} > 2^{Mk+l}$.

The Complexity of the Attacks based on Theorem 7.4

Let $d = \lceil k\lceil(l+1)/m\rceil/2 \rceil$ be the degree obtained in Theorem 7.4. Following Section 6.1, the complexity of the first step of the attack (to find the equations) will be about $2^{\omega(Mk+l)} = 2^{\omega(k\lceil(l+1)/m\rceil+l)}$ and this is roughly $(2^{\omega(d/2+l)})$. For the second step the complexity will be about $\binom{n}{d}^\omega \approx n^{d\omega}$ (see Section 3). Though this d is not always the best degree we will get and use in an attack, we expect that when $m < k$ the complexity of the first step of the attack will frequently be substantially smaller than for the second step (cf. examples in Table 2).

² If, in addition we have $m \geq k$, it could be even better to increase M , see Section 7.6.

7.6 How to Use Theorem 5.1 when $m \geq k$

If $m \geq k$, then when $M \rightarrow \infty$ we can always satisfy the key inequality (K).

$$2^{Mm} \cdot \sum_{i=0}^d \binom{Mk}{i} > 2^{Mk+l} \quad (K)$$

This fact is obvious when $m > k$ and still true when $m = k$, because then it is sufficient to take $M = \lceil (l+1)/k \rceil$ and $d = MK$. (Remark: here M cannot be smaller than $\lceil (l+1)/k \rceil$ because following Section 7.2, $M \geq \lceil (l+1)/m \rceil$ and here it is equal to $\lceil (l+1)/k \rceil$.)

It can be seen that in all cases when $m \geq k$, when $M \rightarrow \infty$, then d may be an arbitrarily small integer > 0 (i.e. we will even get $d = 1$ when M is large enough).

In practice, we should take M as big as possible, but not too big because the complexity to find the equations (Step 1 of the attack) will become too big: it is following Section 6.1 about $2^{\omega(Mk+l)}$ computations. (While Step 2. requires about $\binom{n}{d}^{\omega} \approx 2^{\omega \log_2 nd} / d!$.)

In order to get the best attack, we need to minimise $2^{\omega(Mk+l)} + 2^{\omega \log_2 nd} / d!$ under the condition $\binom{Mk}{d} > 2^{M(k-m)+l}$. The behaviour of these complexities is not simple, because $M \geq \lceil (l+1)/m \rceil$ and must be an integer. Sometimes $M = \lceil (l+1)/m \rceil$ is optimal, sometimes it isn't. Sometimes the best attack will be when both complexities are about equal, sometimes the first step will always take much more time than the second step (even for the minimal $M = \lceil (l+1)/m \rceil$). Some relevant examples are given in Table 3 and Table 2.

7.7 Summary or How To Design the Best Algebraic Attack

In order to find the fastest attack with Theorem 5.1, we recommend to proceed as follows:

- First we try to apply Theorem 7.4, and get a (working) solution (M, d) .
- Then with same M , take the lowest d such that the key condition (K) still holds.
- In addition, when $m \geq k$, as long as the complexity of the first step of the attack is less than the complexity of the second step, we may try to increase M , compute the lower possible d , and see if we get a better result (Cf. Section 7.6).

8 Application to Some Known Stream Cipher Constructions

8.1 Application to modified LILI-128

Our attack can be applied to the second component of LILI-128 cipher [28]: we have an LFSR with $n = 89$ bits, and a Boolean function with $k = 10$ inputs. There is no memory bits ($m = 0$). In [10], a generic attack on LILI-128 is given, that requires $n^{5\omega}$ computations, (whatever is the Boolean function used). From our Theorem 5.1 we see that if in LILI we use simultaneously several Boolean functions, the complexity of the generic attack will substantially decrease. It will be $\binom{n}{d}^{\omega}$ with d given by Theorem 5.1. The resulting degree d quickly decreases with m :

m	1	2	3	5	7
d	5	4	3	2	1

Following closely [10], each of these attacks on the second component of LILI-128 can be transformed into an attack on the whole LILI-128 cipher in two possible ways. Either (A:) the complexity is multiplied by 2^{39} (one needs to guess the 39-bit state of the clocking component), or (B:) the keystream requirements are multiplied by about 2^{39} (at each step the first component is clocked $2^{39} - 1$ times). See [10] for more details. This gives the following generic attack on modified LILI-128 with several outputs:

Table 1. Generic attacks on modified LILI-128 with m outputs

m	1	2	3	5	7					
M	1	1	1	1	1					
d	5	4	3	2	1					
keystream	2^{25}	2^{64}	2^{21}	2^{60}	2^{17}	2^{56}	2^{12}	2^{51}	2^6	2^{45}
time(Step 1.)	2^{25}	2^{25}	2^{25}	2^{25}	2^{25}	2^{25}	2^{25}	2^{25}	2^{25}	2^{25}
time(Step 2.)	2^{107}	2^{68}	2^{95}	2^{56}	2^{83}	2^{44}	2^{69}	2^{30}	2^{54}	2^{15}

We see that for ciphers that combine LFSR and Boolean functions, such as LILI-128, if we replace a Boolean function by a component that outputs a few bits at a time, the security will be dramatically reduced, and this for any component (worst case).

Note: There are attacks on LILI-128 itself, that are faster than the generic attack given here for $m = 1$, see [10, 11]. However for some of the modified versions of LILI-128 with many outputs, our attack will probably be the fastest general attack known on such ciphers.

8.2 Application to modified E0

For the basic component of the stream cipher E0, we have $n = 128$, $k = 4$, $l = 4$, $m = 1$. The Krause-Armknecht theorem gives $d = 10$, see [2]. With our Theorem 5.1 we get the following results:

Table 2. Generic attacks on modified E0 with m outputs

m	1	2	3	4	5	6
M	5	3	2	3	1	1
d	10	5	3	2	2	1
keystream	2^{48}	2^{28}	2^{18}	2^{13}	2^{13}	2^7
time(Step 1.)	2^{64}	2^{42}	2^{30}	2^{30}	2^{19}	2^{19}
time(Step 2.)	2^{131}	2^{76}	2^{49}	2^{33}	2^{33}	2^{16}

We see that for ciphers that combine LFSRs and a combiner with 4 inputs, and 4 memory bits, such as E0, if one outputs several bits at a time (computed in an arbitrary way), the complexity of the attack and the keystream amount required dramatically decreases.

Note: There are attacks on E0 itself, that are faster than the generic attack given here for $m = 1$, see [2, 1, 11]. However for some of the modified versions of E0 with many outputs, our attack will probably be the fastest general attack known.

8.3 Application to Snow and Modified Versions of Snow

We consider both Snow and Snow 2.0. that have an LFSR with $n = 512$ bits that is connected to a stateful combiner that outputs $m = 32$ bits at a time. We obtain:

1. In Snow 1.0. we have $k = 64, l = 64$ and $m = 32$. With Theorem 7.4 we get $M = \lceil (l + 1)/m \rceil = 3$ and $d = \lceil kM/2 \rceil = 96$ that can be lowered to $d = 54$ and still satisfies the requirements of the Theorem 5.1 (for reasons explained in Section 7.5).
2. Similarly, in Snow 2.0. we have $k = 96, l = 64$ and $m = 32$. With Theorem 7.4 we get $M = \lceil (l + 1)/m \rceil = 3$ and $d = \lceil kM/2 \rceil = 144$ that can be lowered to $d = 92$.

These degrees are by far too large to give any hope for practical attacks on Snow.

Algebraic Attacks on Modified Snow

We will look how the complexity of the attack on Snow 1.0. and 2.0. when the number of output bits increases. This could arise if, in order to build a faster cipher, we add to Snow some **arbitrary** S-boxes or Boolean functions that derive some additional output bits, from the k inputs and the l memory bits of Snow combiner.

Since the size of LFSR is 512 bits, an attack will be considered significant if it takes less than 2^{512} . (We study academic attacks on modified Snow, and do not claim to break the actual Snow in which the key is expanded from a shorter key of 128 or 256 bits.)

Table 3. Generic attacks on modified Snow ciphers with m outputs

Snow 1.0. $n = 512, l = 64, k = 64$							Snow 2.0. $n = 512, l = 64, k = 96$					
m	32	64	65	80	100	120	m	32	64	65	120	150
M	3	2	1	1	1	1	M	3	2	1	1	1
d	54	16	32	16	7	2	d	92	35	48	9	2
keystream	2^{245}	2^{99}	2^{169}	2^{99}	2^{51}	2^{17}	keystream	2^{344}	2^{352}	2^{226}	2^{62}	2^{17}
time(Step 1.)	2^{715}	2^{536}	2^{356}	2^{356}	2^{356}	2^{356}	time(Step 1.)	2^{985}	2^{715}	2^{446}	2^{446}	2^{446}
time(Step 2.)	2^{684}	2^{276}	2^{471}	2^{276}	2^{139}	2^{45}	time(Step 2.)	2^{962}	2^{503}	2^{631}	2^{172}	2^{45}

We see that when the number of outputs increases, the security of the cipher collapses. The complexity of the first step of the attack may be $< 2^{512}$ but remains very high. However, one should not think that Snow with added outputs will be very secure: we only gave here the complexity of the generic method to find a useful equation. For a specific cipher, in many cases, there could be a much faster method that exploits the description of the cipher, and will give one multivariate equation, exploited by the main attack (Step 2.). The second step is already very fast.

Note: Our attacks are very general. For the original cipher Snow 1.0. itself, much faster attacks are known, see [6, 5, 19].

8.4 Application to a Modified Turing Cipher

Turing is a stream cipher proposed in 2003 by Rose and Hawkes [26]. It is a new kind of stream cipher which outputs many bits at a time, and in which the combiner is key-dependent. We have $n = 17 * 32 = 544, m = 5 * 32 = 160, l = 0$ (no memory),

$k = 9 * 32 = 288$. These values are very large and any attack faster than the exhaustive search of all possible states $2^n = 2^{544}$ should be considered as interesting.

We will study a modified version of Turing, in which the combiner is NOT key-dependent. Then with Theorem 7.4 we get $M = \lceil (l + 1)/m \rceil = 1$ and $d = \lceil kM/2 \rceil = 160$ that can be lowered to $d = 37$ and still satisfies the requirements of the Theorem 5.1 (for reasons explained in Section 7.5). This degree $d = 37$ is still by far too large to give any hope for practical attacks on Turing. We get an attack on modified Turing with $\text{time}(\text{Step 1.}) = 2^{805}$ and $\text{time}(\text{Step 2.}) = 2^{534}$. The second step is faster than the exhaustive search which would be in 2^{544} . The first step can also probably be improved to be faster than 2^{544} .

9 Extension to Ciphers With Unknown or Key Dependent Combiners

The results of this paper can be also applied to ciphers in which the combiner is only partially known (or key dependent). For example, at some place inside the combiner we XOR the data with the secret key. Or, we use Boolean functions with some coefficients being unknown or key-dependent. Let l' be the total number of unknown bits in the combiner with parameters (k, l, m) . Then we may just consider this cipher as a cipher in which the combiner is known with parameters $(k, l + l', m)$: we just have l' additional memory bits that are not updated, they remain the same all the time. All the attacks described in the present paper will apply and if l' is not too big, or when $m \geq k$, they may be efficient.

10 Conclusion

In this paper we studied generic algebraic attacks on stream ciphers built with an LFSR and a combiner having a small number of memory bits. Our main result is that the complexity of the general attack proposed in [2] and in less general version in [10], will substantially decrease if the cipher outputs several bits at a time. Moreover we gave a much simpler proof of the important Theorem of [2].

Our Theorem is illustrated on modified versions of three well known stream ciphers E0, LILI-128 and Snow. The complexity of algebraic attacks on these ciphers will dramatically decrease, if we increase the number of bits that are output at a time. We demonstrated the existence of (yet another) very general tradeoff between speed and security of stream ciphers with (and without) memory.

A Another Proof of Theorem 4.1 in a Stronger Version

In this appendix we give another proof of Theorem 4.1 and show that, for the same degree, much less monomials need to be included in the equations. This improvement is not at all obvious, neither from our previous proof of Theorem 4.1, nor from its proof resulting from [2].

Theorem A.1 (Strong Version of the Special Case of Krause-Armknecht Theorem).

Let F be an arbitrary fixed circuit with k binary inputs x_i , one bit of memory a , and one output y . Then, given $M = 2$ consecutive states $(t, t + 1)$, there is a multivariate relation of degree k in the $x_j^{(i)}$, that relates only the input and the output bits, **without** any of the state/memory bits $a^{(t)}, a^{(t+1)}$:

$$R(x_0^{(t)}, \dots, x_{k-1}^{(t)}) + y^{(t)} \cdot S(x_0^{(t)}, \dots, x_{k-1}^{(t)}) + \\ + T(x_0^{(t+1)}, \dots, x_{k-1}^{(t+1)}) + y^{(t+1)} \cdot U(x_0^{(t+1)}, \dots, x_{k-1}^{(t+1)}) = 0.$$

Proof: We have $m = l = 1$. To prove this result, we will prove that basically the same type of result is true also for any m , provided that we have $m = l$ (or more).

This new theorem, will give the same M and the same d than our most general Theorem 7.4. Yet it exhibits equations that use much less monomials (and thus easier to find).

Theorem A.2 (Strong Version of Theorem 5.1 when $m = l$).

Let F be an arbitrary component with k binary inputs x_i , l bits of memory a , and m outputs y_i with $m = l$. Then, given $M = 2$ consecutive applications of the component $(t, t + 1)$, there is a multivariate relation (being of degree k in $x_j^{(i)}$) of the form:

$$R(x_0^{(t)}, \dots, x_{k-1}^{(t)}, y_0^{(t)}, \dots, y_{k-1}^{(t)}) = S(x_0^{(t+1)}, \dots, x_{k-1}^{(t+1)}, y_0^{(t+1)}, \dots, y_{k-1}^{(t+1)}).$$

Proof: First we consider only one state, at time t . The output bits $y_i^{(t)}$ the next memory bits $a_i^{(t)}$ do depend only on the previously existing memory bits $a_i^{(t-1)}$, and the k inputs $(x_0^{(t)}, \dots, x_{k-1}^{(t)})$. We have 2^{k+l} possibilities. We consider the following matrix: Line are all the 2^{k+l} possibilities, and columns are all the 2^{k+l} monomials of type $\prod x_i^{(t)} \cdot \prod y_j^{(t)}$.

We have now 2^{k+l} lines and also $2^{k+m} = 2^{k+l}$ columns.

Let $Q(x_0^{(t)}, \dots, x_{k-1}^{(t)}, a_0^{(t-1)}, \dots, a_{l-1}^{(t-1)})$ be an arbitrary function. We add one more column to the matrix, in which we put the values of $Q()$. We get the matrix with 2^{k+l} lines and $2^{k+l} + 1$ columns, and we know that a linear dependency must exist between the columns, whatever is the function $Q()$. In this linear dependency the last column $Q()$ may or may not appear, which we denote by $[Q(x_0^{(t)}, \dots, x_{k-1}^{(t)}, a_0^{(t-1)}, \dots, a_{l-1}^{(t-1)})]$.

By definition, all the other columns are monomials, and their linear combination is a polynomial. Therefore, for every Boolean function Q , our dependency means that there exist a multivariate polynomial R such that:

$$\begin{aligned} R\left(x_0^{(t)}, \dots, x_{k-1}^{(t)}, y_0^{(t)}, \dots, y_{k-1}^{(t)}\right) &= \\ &= \left[Q\left(x_0^{(t)}, \dots, x_{k-1}^{(t)}, a_0^{(t-1)}, \dots, a_{l-1}^{(t-1)}\right)\right]. \end{aligned}$$

(As explained above, $[\alpha Q(\dots)]$ means $\alpha Q(\dots)$ with $\alpha = 0$ or 1).

For any Q , we may in explicitly compute this polynomial for step t . We may put for example, for any i , $Q\left(x_0^{(t)}, \dots, x_{k-1}^{(t)}, a_0^{(t-1)}, \dots, a_{l-1}^{(t-1)}\right) = a_i^{(t-1)}$ but also $Q(\dots) = a_j^{(t)}$ for any j . Indeed both the previous and the current memory bits are a deterministic function of these $k + 1$ variables. (Hence, for example we may not put $Q(\dots) = a_0^{(t+1)}$.) In our proof, for step t , we will use the first bit of the first state: $a_0^{(t)}$. Then for $t + 1$, we are allowed to use the same bit, since $a_0^{((t+1)-1)} = a_0^{(t)}$ (but not for the following steps anymore). Then we will eliminate $a_0^{(t)}$. More precisely, we do the following:

Let $Q(\dots) = a_0^{(t)}$, there exists R such that

$$R\left(x_0^{(t)}, \dots, x_{k-1}^{(t)}, y_0^{(t)}, \dots, y_{k-1}^{(t)}\right) = \left[a_0^{(t)}\right] \quad (1)$$

Now, for the next step $t + 1$, let $Q'\left(x_0^{(t+1)}, \dots, x_{k-1}^{(t+1)}, a_0^{(t)}, \dots, a_{l-1}^{(t)}\right) = a_0^{(t)}$, and we know that there is another polynomial S such that:

$$S\left(x_0^{(t)}, \dots, x_{k-1}^{(t)}, y_0^{(t)}, \dots, y_{k-1}^{(t)}\right) = \left[a_0^{(t)}\right] \quad (2)$$

With these two equations (1) and (2) we may always eliminate $a_0^{(t)}$ and we get the claimed result. \square
